Abstract: The prevalence of Diabetes mellitus (DM) is continuously rising worldwide. Among its types, type I is characterized by the destruction of beta cells triggered by various mechanisms, including the activation of Caspase 3. Studies have demonstrated the crucial role of Caspase 3 in initiating the apoptosis of beta cells in DM. Our research aims to identify possible phytocompounds inhibitors of Caspase 3 using computational approach. We obtained 3D structures of Caspase 3 and 6511 phytocompounds from the Protein Data Bank and the African Natural Products Database, respectively. The phytocompounds were assessed for druglikeness properties, topological polar surface area, and preliminary toxicity using DataWarrior. The phytocompounds were subjected to molecular docking simulation (MDS) at Caspase 3 active site using AutoDock-Vina. The frontrunner phytocompounds obtained from the MDS were subjected to protease inhibition prediction on Molinspiration. The pharmacokinetics of the phytocompounds were assessed on SwissADME. The in-depth computational toxicity profile of the phytocompounds was evaluated on the pkCSM web. The binding interactions of the phytocompounds with Caspase 3 were assessed with Discovery Studio Visualizer and Maestro. Seventeen phytocompounds were found to have no violation of Lipinski's rule and had no toxicity based on the preliminary assessment, have better binding affinity and protease inhibitory prediction scores than the references, have optimistic bioactivity radar prediction and similar amino acids interaction, in comparison with the references. Further studies, which include *in-vitro* and *in-vivo* studies, will be carried out to validate the results of this study.

1. Introduction

Beta-cell apoptosis is a critical event in the pathogenesis of type 1 diabetes mellitus (DM). Aside from being the primary mechanism by which cells are destroyed, beta-cell apoptosis has been linked to the onset of type 1 DM via antigen cross-presentation mechanisms that result in beta-cell-specific T-cell activation (1). Apoptosis can be activated via the extrinsic death receptor or intrinsic mitochondrial pathway, activating effector caspases (2). Apoptosis is also a critical process in the development of atherosclerosis (2).

Caspases are endoproteases and genes crucial for preserving homeostasis by controlling cell death and inflammation. A phylogenetically conserved death program that is essential for the homeostasis and growth of higher organisms carefully regulates their activation. Numerous human diseases are primarily pathogenetic due to the dysregulation of apoptosis. Caspases are potential therapeutic targets because they are part of the apoptotic machinery (3, 4).

Caspases are classified broadly according to their known roles in apoptosis (caspase-3, -6, -7, -8, and -9 in mammals) and inflammation (caspase-1, -4, -5, -12 in humans and caspase-1, -11, and -12 in mice). Caspase-2, -10, and -14 functions are more difficult to classify. Caspases involved in apoptosis have been divided into two groups based on their mechanism of action: initiator caspases (caspases - 8 and -9) and executioner caspases (caspase-3, -6, and -7) (3).

In a study titled "Caspase-3-Dependent -Cell Apoptosis in the Initiation of Autoimmune Diabetes Mellitus", the authors used a genetic approach to show that this process is necessary for cross-presentation of beta-cell antigen to activate beta-cell-specific T cells (1). They proved that mice lacking caspase-3 do not experience the onset of autoimmune diabetes, which is indicated by normal level of glucose concentration in the blood, unaffected beta-cells revealing high insulin content, and absence of beta-cell specific T-cell activation in the pancreatic draining lymph nodes. In a different study titled "Immunocytochemical localization of caspase-3 in pancreatic islets from type 2 diabetic subjects", the author reported finding more cleaved caspase-3 immunostained islets from type 2 diabetics, which may indicate an accelerated apoptotic cascade in the islets, along with increasing amyloid deposition before ultimate cell death (5).

The improper control of caspase-mediated cell death and inflammation is linked to various illnesses, including inflammatory, neurological, and other metabolic diseases and cancer. It may be necessary to therapeutically target caspase-3 activity in cells to stop the onset of autoimmune diabetes (1). Numerous natural and synthetic caspase inhibitors have been discovered and created to be used therapeutically. Only a few synthetic caspase inhibitors have progressed into clinical trials due to their lacklustre efficacy or harmful side effects. They have yet to prove compelling enough for patient use (6).

The aim of this study is to detect phytocompounds with drug like properties in African plants that could inhibit Caspase-3 through *in-silico* analysis.

2. Materials and Methods

2.1 Materials

The materials used are personal computer, African Natural Compounds Database, PubChem (http://Pubchem.ncbi.nlm.nih.gov) (7), Linux operating system (Ubuntu desktop 18.04), Protein data bank (https://www.rcsb.org/) (8), DataWarrior software (9), PyMOL software (10), AutoDockTools-1.5.6 software (11), AutoDock Vina 1.1.2 software (12), on Ubuntu operating system, and Molinspiration Chemoinformatics web tool (https://www.molinspiration.com/cgi-bin/properties) (13).

2.2 Literature Mining

To find essential targets and receptors for apoptotic processes, literatures were explored. This was done to examine the role of the target and receptors in the pathophysiology and initiation of cell apoptosis. This provides more details regarding the receptor's characteristics, activities, and druggability.

2.3 Selection and Preparation of the Receptor

Caspase 3 in 3D format was retrieved from Protein Data Bank (PDB) with the PDB ID: 3KJF after various targets and receptors had been identified, literature had been mined, and the target and receptor had been analyzed. PyMOL program was initially used to prepare the pdb file by selecting the necessary chains and deleting multiple ligands. To understand how the ligands attach to receptors, PyMOL software was used. The AutoDockTools was used to get the receptor ready for molecular docking simulations. The receptors were prepared by adding polar hydrogens and Kollman's charges before storing them in the pdbqt file format, the structural format needed for performing molecular docking simulation on Autodock Vina. As shown in Table 1, the electrostatic grid boxes and the three-dimensional affinity with various sizes and centers were formed around the protein's active region.

Table 1. Grid box parameters used for the molecular docking simulations

	3KJF	
	Centres	**Sizes**
X	21.94	14
Y	-4.306	14
Z	10.718	14

2.4 Selection of the Ligands

In this study, 6511 phytocompounds were examined, which were obtained from the African Natural Products Database (African-compounds.org) (14, 15). The compounds were downloaded as 3D-structure data files for analysis. Various parameters such as partition coefficient (Log P), topological polar surface area (TPSA), molecular weight, hydrogen bond donor, and hydrogen bond acceptor were used to assess the phytocompounds. Some of the phytocompounds were found to infringe Lipinski's rule. Those that did not breach the rule underwent toxicological assessment for mutagenicity, carcinogenicity, tumorigenicity, and reproductive effect.

2.5 Preparation of the Ligands

Phytocompounds with no Lipinski's rule of five infarctions and no predicted toxicity (mutagenicity, carcinogenicity, tumorigenicity, and reproductive effect) *in-silico* were prepared for the molecular docking simulation. Reference ligands were identified from the literature, including the compound co-crystallized with the receptor/protein on the PDB database. In preparation for the ligands for molecular docking simulation, all rotatable bonds, torsions, and Gasteiger charges were assigned and saved in the pdbqt file format.

2.6 Validation of Docking Protocol

The PDB structure of the 3KJF (Caspase 3) protein, in association with a reference inhibitor as was downloaded from the PDB, was replicated *in-silico* to validate the molecular docking simulations procedure for this protein. Other known inhibitors of Caspase 3 were also used for the validation, including Flubendazole, Fenoprofen, Pranoprofen, and Diflunisal (16). The AutoDockTools-1.5.6 was used to calculate polar hydrogen, Kollman charges, grid box sizes, and centers at a grid space of 1.0 (11, 12). The protein was stored as a pdbqt file. AutoDockTools-1.5.6 was used to prepare the reference chemicals for molecular docking simulation. Torsion-free bonds, as well as any other rotatable bonds, were permitted. After that, files with the pdbqt extension were generated as output. On a Linux environment, a virtual screening shell script was used to locally implement the AutoDock Vina® molecular docking simulation of the protein and reference chemical utilizing the centers and sizes (12). Co-crystal inhibitor binding interaction was compared with the re-docked

co-crystalized compounds, Flubendazole, Fenoprofen, Pranoprofen, and Diflunisal using PyMol-1.4.1 software and Discovery studio visualizer.

2.7 Molecular Docking of the Phytocompounds on Caspase 3

The phytocompounds were prepared in batches for molecular docking simulations using virtual screening scripts against the Caspase 3. Following the validation of docking methods, four replicates of Molecular Docking Simulations were performed on a Linux platform using AutoDock Vina® and related tools. To determine the leading phytocompounds, binding free energy values (kcal/mol SD) were ranked.

2.8 Bioactivity Prediction of Phytocompounds

The online Molinspiration web tool version 2011.06 (www.molinspiration.com) was supplied SMILES notations of the leading phytocompounds to forecast the bioactivity scores for protease inhibition.

2.9 Computational Pharmacokinetics of Frontrunner Phytocompounds

The top phytocompounds underwent a thorough pharmacokinetics evaluation using SwissADME, a web-based tool that assesses the druglikeness, physicochemical, ADME properties, and medicinal chemistry compatibility of small molecules (17). The assessment was conducted to examine the pharmacokinetics of the lead phytocompounds in detail.

2.10 In-depth Toxicity Assessment of Frontrunner Phytocompounds

An in-depth toxicity prediction of the frontrunner phytocompounds for AMES toxicity, Max. tolerated dose (human), hERG I inhibitor, hERG II inhibitor, Oral Rat Acute Toxicity (LD_{50}), Oral Rat Chronic Toxicity (LOAEL), Hepatotoxicity, Skin Sensitization, *T. Pyriformis* toxicity and Minnow toxicity on the pkCSM platform (18).

2.11 Analysis of the Frontrunner Phytocompounds-Caspase 3 Binding Interactions

The amino acids of Caspase 3 binding interactions with each frontrunner phytocompounds were analyzed using Discovery Studio Visualizer v20.1.0.19295, and Maestro 13.3 aided the generation of 2D structures of the interaction for easy observation (19, 20).

3. Results

3.1 Preliminary Drug-likeness and Toxicity Assessment of the Ligands (Phytocompounds)

The drug-likeness assessment of the 6511 phytocompounds was performed using Lipinski's rule of five to screen out phytocompounds that violated the guidelines on the DataWarrior application. Following the screening, 3814 phytocompounds had no infraction of Lipinski's rule, but 2697 phytocompounds did. Toxicity testing on the 3814 phytocompounds that did not violate Lipinski's criteria was performed using DataWarrior to discover phytocompounds that could be mutagenic, tumorigenic, irritating, or have reproductive implications. *In-silico* testing revealed that 1897 phytocompounds possessed none of the identified toxicities. The total polar surface area (TPSA) was also calculated for each phytocompounds.

3.2 Validation of docking protocol

The docking procedure was validated to assure the *in-silico* repeatability of the experimental protein-ligand interactions gathered from the protein data bank and to observe Caspase 3 amino-acids-conventional hydrogen bond interactions with the reference compounds known as inhibitors of caspase 3. Table 2 shows the binding energy of the docked co-crystalized ligand and that of the reference known inhibitors of caspase

3. Figure 2 is the 2D representation of the docked co-crystalized ligand and reference compounds with the specific Caspase 3 amino acids involved in the interaction. Table 3 shows each reference compound, docked co-crystalized ligand, and the docked co-crystalized ligand with the specific amino acids involved in their interaction with caspase 3.

Table 2. Mean binding energies of the docked co-crystalized ligand and reference compounds

No.	Reference compounds	Mean Binding Affinity	Standard Deviation
1	Flubendazole	-7.60	0.20
2	Diflunisal	-7.20	0.00
3	B92 (Co-crystalized)	-7.13	0.15
4	Pranoprofen	-6.50	0.00
5	Fenoprofen	-6.18	0.05
Figure 1. 2D representations of the docked co-crystalized ligand and reference compounds amino acids interaction

Table 3. Mean binding energies of the docked co-crystalized ligand and reference compounds

No.	Reference compounds	Amino acids
1	B92	ARG 207,SER 205, SER 209
2	B92 (Co-crystalized)	ARG 207, SER 209, PHE 250
3	Diflunisal	ASN 208, SER 209
4	Pranoprofen	ASN 208
5	Fenoprofen	SER 209
6	Flubendazole	ARG 207, ASN 208, PHE 250

3.3   Molecular Docking of the Phytocompounds against Caspase 3

To identify phytocompounds with greater in silico binding energies against Caspase 3 than the co-crystalized ligand and reference compounds, molecular docking of the phytocompounds was carried out on Caspase 3. The result is presented in table 4, showing phytocompounds with higher mean binding energies than the co-crystalized ligand and reference compounds. The table also contains Lipinski's rule parameters and TPSA values of the phytocompounds.

Table 4. Phytocompounds with better mean binding affinities than the reference compounds

3.4 Bioactivity Prediction of Phytocompounds

Because Caspase 3 is a protease, the phytocompounds were screened computationally on Molinspiration for their ability to inhibit protease. According to the results, 80 phytocompounds were discovered to have computational protease inhibitory scores below the co-crystalized ligand (B92) and above the four other reference compounds used (Flubendazole, Pranoprofen, Fenoprofen, and Diflunisal). Table 5 below shows the outcomes of the bioactivity prediction of the phytocompounds with higher binding energies than the co-crystalized ligand and reference compounds. One of the phytocompounds, as shown in table 5, has a bioactivity score above Pranoprofen, Fenoprofen, and Diflunisal but below B92 and Flubendazole.

## 3.5 Computation Pharmacokinetics of Frontrunner Phytocompounds

The results of the pharmacokinetic assessment of the frontrunner phytocompounds, reference compounds, and co-crystalized are presented below in figure 2. The results are shown in bioavailability radar graphics. The components of the pictures below include Lipophilicity (LIPO), size, polarity (POLAR), solubility (INSOLU), flexibility (FLEX), and saturation (INSATU). According to the result, the reference compounds and co-crystalized ligands failed the bioavailability radar test. Out of the 82 phytocompounds assessment, 18 were within the optimal range of the bioavailability radar test.

3.7 Analysis of the Frontrunner Phytocompounds-Caspase 3 Binding Interactions

The binding interactions between the frontrunner phytocompounds and Caspase 3 were analyzed using Maestro 13.3 and Discovery studio visualizer. The results are presented in figure 3 and table 7. The result shows the specific amino acids (with arrow) that contributed to the conventional hydrogen bond interaction between the frontrunner phytocompounds and Caspase 3.

4. Discussion

The study aimed to use *in-silico* molecular docking simulation to compare the binding affinities of phytocompounds from the African natural product database to the reference compounds against Caspase 3. The phytocompounds should have no violation of Lipinski's rule of five, with no predicted toxicity and positive bioactivity score. Due to the high cost of drug discovery and development and the required time, creating new medications has proven challenging. The "*in-silico*" method of drug discovery and design, also known as computer-aided drug design, is now widely used in preliminary research to minimize the chances of compound failure in the later stages of drug development. Computer-aided drug design components like molecular docking, molecular dynamics, quantitative structure-activity relationship, absorption, distribution, metabolism, excretion, and toxicity tool and their precise predictions speed up the discovery and development of new drugs (21, 22)

On the other hand, medicines and medicinal substances have historically been derived from nature, primarily plants. Plant extracts have been evaluated for different pharmacological activities with promising results (23, 24). Most medicines today are either isolated or created from isolates derived from natural sources. Based on their use in conventional medical procedures, most currently utilized medications are made from natural sources (25). More novel compounds are being isolated from plants and deposited in chemical databases (26). There are also general biological and specialized databases on which thousands of proteins are deposited to aid scientific research (22).

During drug design and development, pharmaceutical chemists frequently use Lipinski's rule of five to predict the oral bioavailability of potential lead or pharmacotherapy compounds. This study obtained 6511 phytocompounds reportedly isolated from African plants from the African natural product database. The drug-likeness of these phytocompounds was determined based on Lipinski's rule of five, using DataWarrior. According to Lipinski's rule of five, a compound is more probable to be orally effective if it satisfies the following basic requirements: a) has a molecular weight of less than 500; b) has a projected octanol/water partition coefficient (Log P less than 5); c) contains no more than five hydrogen bond donors; and d) contains no more than ten hydrogen bond acceptors (27–29). Of the 6511 phytocompounds we started with, 3814 showed no violation of Lipinski's rule of five.

The DataWarrior application used for Lipinski's rule and preliminary toxicity assessment employs a precomputed collection of structural pieces that trigger toxicity alerts when discovered in the structures under investigation. To compile these fragment lists, all compounds from the Registry of Toxic Effects of Chemical Substances (RTECS) database known to be active in a specific toxicity class were thoroughly split (30). The phytocompounds were first severed during the process, with each rotating link leading to a set of core fragments. These were then used to reconstruct each substantial substructure of the parent molecule. A substructure search process was then used to determine the frequency of any fragment (core and created fragments) within all chemicals in that toxicity class. It also found these fragment frequencies in the structural data of over 3000 traded medications. Any fragment was considered a risk factor if it was commonly encountered as a substructure of dangerous chemicals but never or only infrequently in traded pharmaceuticals. This assumption was based on the view that most drugs sold are free of or have less toxic effects. Predicated on this described fragments exploration, 1897 phytocompounds had no *in-silico* mutagenicity, tumorigenicity, irritant, or reproductive effects. These phytocompounds contained no fragments or fragments widely recognized to have any of the toxicities enumerated in the Registry of Toxic Effects of Chemical Substances.

As shown in Table 4, the molecular docking findings revealed 120 phytocompounds with higher binding affinity than the reference compounds. Lower binding affinity indicates improved ligand binding. The most significant magnitude negative value, representing the most positive conformation of the complex formed whenever the ligand invested efficiently binds with the protein's active site, determines the significance of binding affinity values. As can be seen, the mean binding affinity scores are negative. This happens because protein-ligand binding occurs solely when the free energy change is negative. The G-level difference between complexed and unconjugated free states is commensurate to the stability of the protein-ligand interaction. Once ΔG is minimal in the system, protein folding and protein-ligand binding occur (31, 32). As a result, negative ΔG scores indicate the stability of the arising complexes with the receptor molecules, a necessary feature of effective drugs (33).

Compounds with better binding affinities than the reference compounds used were subjected to molinspiration bioactivity prediction for protease inhibition since Caspase is a protease. The result of the bioactivity prediction presented in table 5 shows that 82 phytocompounds out of 120 compounds analyzed are active as protease inhibitors based on the range of bioactivity score on the molinspiration platform. In molinspiration, biological activity is measured by a bioactivity score that is categorized as active (0.00 to 0.5), moderately active (0.00 to -0.5), and inactive (less than -0.5) (13).

Bioavailability Radar is displayed for a rapid appraisal of drug-likeness. Six physicochemical properties are considered: lipophilicity, size, polarity, solubility, flexibility, and saturation. A physicochemical range on each axis was defined by descriptors such as size, lipophilicity, H-bonding characteristics, rotatable bond, aromatic ring counts, etc., and depicted as a pink area in which the radar plot of the molecule has to fall entirely to be considered druglike (34, 35). The results of the pharmacokinetic prediction of the frontrunner phytocompounds presented in figure 2, as a bioavailability radar, revealed that only 17 out of 82 phytocompounds analyzed fit optimally into the pink region of the bioavailability radar map.

The 17 phytocompounds with optimal bioavailability radar prediction were subjected to further toxicity prediction on the pkCSM application. The result is presented in table 6 with the predictions of the reference compounds too. Seven parameters were predicted; AMES toxicity, hERG I inhibitor, hERG II inhibitor, Hepatotoxicity, Minnow toxicity, T. Pyriformis toxicity, Max. tolerated dose (human), Oral Rat Acute Toxicity

(LD$_{50}$), and Oral Rat Chronic Toxicity. The Ames test is a procedure that uses the amino acids needed by the bacterial strains Salmonella typhimurium and *Escherichia coli* to identify mutations. This mutation test aims to find revertant bacteria that give the original bacteria its ability to synthesize an essential amino acid back. The revertant bacteria can still grow when the original strain's necessary amino acid is absent (36).

Ames test results have shown that it is susceptible to predicting carcinogens: 80% of Ames evaluation mutagens are also cancerous, while a negative outcome has no discriminatory significance (a chemical negative in Salmonella has the same possibility of being either a non-carcinogen, a non-genotoxic carcinogen, or a genotoxic carcinogen acting through a process not observed by the Ames test (37). In the creation of cardiac action potentials, HERG is crucial. Hence, QT prolongation and unexpected cardiac death are linked to hERG channel inhibition. Due to this significant outcome, evaluating hERG blockade by compounds during the early stages of drug discovery and development is crucial. Using various drug descriptors like log P and log S and modeling techniques like estate fingerprint, CDK fingerprint, and secondary structural fingerprint, this inhibitory effect can be predicted *in-silico* (38). Minnow toxicity is a crucial foundation for risk and hazard analysis of substances in the aquatic system (39). The toxicity of *Tetrahymena pyriformis* is frequently used as a toxic end state. From the result in table 6, Abyssinone I recorded positive for Ames toxicity with one of the reference compounds, Flubendazole. Sipholenol A and Sigmoidin F were predicted positive as hERG inhibitors and Flubendazole. Abyssinoflavone V, Isoferprenin, Beta-anhydroepidigitoxigenin, Tingenin B, Flubendazole, and Pranoprofen were predicted to possess hepatotoxic effects.

The conventional hydrogen bond interaction between the amino acids of Caspase and each of the frontrunner phytocompounds were analyzed as presented in figure 3 and table 7. Observation of the interactions of the reference compounds with Caspase 3, as shown in figure 1 and table 3, reveals the specific amino acids-conventional hydrogen bond interactions, which are probably responsible for the actions of these reference compounds. The amino acids include ARG 207, SER 205, SER 209, ASN 208, and PHE 250. Now, observation of figure 3 and table 7 also reveals the specific amino acids interaction of the frontrunner compound with Caspase 3, similar to those of the reference compounds, except Beta-anhydroepidigitoxigenin, Abyssinone I, 7-deacetoxy-7-oxogedunin, Sigmoidin F and Isoferprenin

Based on the simulation research design, the outcomes of *in-silico* research translate well throughout *in-vitro* or *in-vivo* studies. Before synthetic chemistry synthesis, *in-silico* techniques are frequently used to examine compound libraries' bioavailability, toxicity, and promising bioactivity (40). Similarly to that, we planned the design of the current *in-silico* study to increase the likelihood of getting positive results in bioassays. One of the quickest and most accurate *in-silico* methods for analyzing the molecular interactions and chemical bonding between a ligand and a protein is molecular docking (41). To observe and analyze the molecular interaction and ligand binding of compounds with studied biomarkers, molecular docking research, and *in-vivo* studies are often combined (42–48). This discussion demonstrates the reliability of *in-silico* drug discovery and development studies, supports and validates the methodology used in the current *in-silico* study, and supports the notion that the African natural product database contains promising phytocompounds that could have the potential to act as Caspase 3 inhibitor.

5. Conclusion

Inhibitors of Caspase 3 can offer a remedy for the pharmaceutical intervention of beta-cell apoptosis in diabetes since options for treating beta-cell apoptosis are a significant therapeutic need. In this study, the findings imply that Tribulus saponin aglycone 2, Sonchuside, Abyssinoflavone V, Limonyl, 3-acetylsesterstatin

1, Retusolide B, Tingenin B, Abyssinin I, Uguenensene, Siphonellinol C, Sipholenol A, Sigmoidin F and Limonin and possibly their plant sources are candidates for further studies as Caspase 3 inhibitors. These phytocompounds are predicted to be druglike, with optimal pharmacokinetic parameters. The compounds possess better binding energies than the reference compounds used for the study. The phytocompounds also have similar conventional hydrogen bond interaction with Caspase 3 compared to the reference compounds. Validating this *in-silico* work requires further thorough research using different models, such as in-vitro and in-vivo assays using the phytocompounds or extracts containing the phytocompounds. Restate the problem, summarize the paper, and discuss the implications and future research direction. This conclusion must address the objective of the study.
